

Post-shock Volatility Forecasting Using Aggregated Shock Information

David Lundquist*, Daniel Eck†

Department of Statistics, University of Illinois at Urbana-Champaign

Dec 6th, 2023

Abstract

We develop a novel procedure for forecasting the volatility of a time series under study immediately following an exogenous shock. Adapting the synthetic prediction framework of [Lin and Eck \[2021\]](#), we exploit series that have experienced similar shocks. We aggregate their shock-induced excess volatilities by positing the shocks as affine functions of exogenous covariates. The volatility shocks are modeled as random effects and estimated as fixed effects. The aggregation of these estimates is done in service of adjusting the h -step-ahead GARCH forecast of the time series under study by an additive term. The adjusted and unadjusted forecasts are evaluated using three families of benchmarks: the unobservable but easily-estimated realized volatility (RV) of the time series under study, implied volatility, and the empirical volatility over horizons of varying length. We also compare the performance of the adjusted forecast to the performance of the Realized GARCH forecast, which is known to react faster to rapidly-changing volatility than GARCH incorporating implied volatility. Finally, we combine Realized GARCH modeling with the synthetic prediction framework, using Realized GARCH in both the estimation of random effects as well as the forecast for the time series under study. Real-world illustrations are provided, as are simulation results suggesting the conditions under which our approach's hyperparameters can be tuned for best performance.

1 Introduction

The most important stochastic phenomenon of many time series $(P_t)_{t \in \mathbb{N}}$, especially financial time series, is the volatility of the return series $(r_t)_{t \in \mathbb{N}}$. A financial asset's price series and daily return series may exhibit behavior that makes inapplicable and uninterpretable the traditional methods of time series analysis. In contrast, the return series is scale-free [[Tsay, 2005](#)], easily-interpreted, and often at least weakly stationary. Yet even if one could model and forecast price series and return series with high accuracy, that would not necessarily tell us much about the variability of such forecasts nor enlighten us about the evolution of the variability of $(P_t)_{t \in \mathbb{N}}$ over time. Modern portfolio management and theory requires information about at least the first two moments of a return series, if not higher. For these reasons and others, volatility modeling has come to dominate financial econometrics over the past four decades.

However, no matter how a time series or its transformations are modeled, forecasting in the presence of exogenous shock events requires a methodological framework that sensibly incorporates relevant information that has yet to manifest in market price or derivative quantities like volatility. In this setting, regime-change models are of little use because under the assumption of a known exogenous shock, there is no need to estimate a regime-change time, nor is there data following the exogenous shock event to

*davidl11@illinois.edu

†dje13@illinois.edu

fit a model. Asymmetric GARCH models were an early attempt to account for fact that negative returns typically beget larger volatility than positive returns [Hansen et al., 2012]. As a separate problem, GARCH models have been shown slow to adapt to spikes in volatility [Andersen et al., 2003]. Engle [2002] explored the use of implied volatility as an exogenous regressor in a GARCH model, that is, using a so-called GARCH-X model [Sucarrat, 2020]. Hansen et al. [2012] propose Realized GARCH, which aims to solve both the asymmetry problem as well as the slow-reaction problem by introducing a “measurement equation” as a tool for modeling the contribution to the conditional variance made by the market-implied volatility measure. The key insight is that the market-implied volatility measure is not independent of the conditional variance posited by the GARCH model. Therefore, including the external measure must be done in a way that accounts for this dependence.

The approach herein can be viewed as an attempt to sidestep the functional complexity posited by Realized GARCH by substituting modeling assumptions. Synthetic Volatility Forecasting proceeds under the assumption that similar unscheduled news events occasion volatility shocks arising from a common shock distribution.

Figure 1: A simulated example of shock aggregation using the arithmetic mean of donor fixed effect estimates.

As we see in Figure 4, the arithmetic mean of estimated shock effects provides perhaps the most straightforward and intuitive way of aggregating information from similar events. Aggregating forecasts using the arithmetic mean is more than merely intuitive; it possesses an empirical pedigree and is known to be optimal under rather restrictive conditions [Timmermann, 2006]. Synthetic volatility forecasting lacks these restrictions and instead assumes a credible, parsimonious parameterization in which the shock is an affine transformation of several key covariates.

2 Literature Review

2.1 Connection to forecast combination methods

What we are combining, if anything, is subcomponents of forecasts, not forecasts themselves. However, from a broader perspective, forecast combination is an inapt term for what is being proposed here. First, the donors are not forecasts.

2.2 Why is the proposal here unlike KNN regression?

In KNN regression, the hyperparameter K must be learned. In Synthetic Volatility Forecasting, the number of donors is not learned. A donor pool is curated, and then careful rules of thumb can be applied to determine whether a given donor should be included or excluded.

2.3 Should we gather as many donors as possible and pick them quantitatively?

It would be counter to the method proposed herein to assemble a vast number of donors, lacking careful scrutiny of the qualitative fit, and let the optimization simply pick the donors, via weighting. What makes a donor good is not merely its quantitative fit but its qualitative fit as well.

2.4 News shock literature review

We adapt the news shock framework of [Kilian and Lütkepohl \[2017\]](#):

$$z_{T^*+1}^{\text{irregular news shock}} := z_{T^*+1}^{\text{irregular news}} - \mathbb{E}_{T^*}[z_{T^*+1}^{\text{irregular news}}]$$

In our adapted schema, irregular news shocks are \mathcal{F}_{T^*} -zero-expectation events governed by a GARCH-X process. As such, $z_{T^*+1}^{\text{irregular news shock}}$ admits of the decomposition $z_{T^*+1} = \sigma_{T^*+1} \epsilon_{T^*+1}$

2.5 Improvements of this current work over its predecessor

This present work extends [Lin and Eck \[2021\]](#) principally by substituting the GARCH model and for modeling both the mean and volatility of a univariate time series. We permit both shocks in the mean model and volatility model of GARCH. As ancillary improvements, the current work permits the shock periods to be of any length, formally $L_{\text{vol}}, L_{\text{level}} \in \mathbb{Z}^+$, and the weights applied to the donor pool can come from more exotic subsets of \mathbb{R}^n .

At a technical level, the most substantial insight related to [Lin and Eck \[2021\]](#) is that the GARCH model provides elegant forecast function for squared observations of the time series under study. To see this, for each i, t , define $\eta_{i,t} := a_{i,t}^2 - \sigma_{i,t}^2$, and by adding $\eta_{i,t}$ to both sides of the conditional variance specification of \mathcal{M}_1 and \mathcal{M}_2 , we obtain the standard ARMA representation of a GARCH(m,s):

$$a_{i,t}^2 = a_{i,t}^2 - \sigma_{i,t}^2 + \sigma_{i,t}^2 = \eta_{i,t} + \sigma_{i,t}^2 = \eta_{i,t} + \omega_i + \omega_i^* D_{i,t} + \sum_{k=1}^{m_i} \alpha_{i,k} a_{i,t-k}^2 + \sum_{j=1}^{s_i} \beta_{i,j} \sigma_{i,t-j}^2 + \gamma_i^T \mathbf{x}_{i,t} \quad (1)$$

$$= \eta_{i,t} + \omega_i + \omega_i^* D_{i,t} + \sum_{k=1}^{m_i} \alpha_{i,k} a_{i,t-k}^2 + \sum_{j=1}^{s_i} \beta_{i,j} (a_{i,t-j}^2 - \eta_{i,t-j}) + \gamma_i^T \mathbf{x}_{i,t} \quad (2)$$

$$= \eta_{i,t} + \omega_i + \omega_i^* D_{i,t} + \sum_{k=1}^{\max\{m_i, s_i\}} (\alpha_{i,k} + \beta_{i,k}) a_{i,t-k}^2 - \sum_{j=1}^{s_i} \beta_{i,j} \eta_{i,t-j} + \gamma_i^T \mathbf{x}_{i,t} \quad (3)$$

Then for any i, t , $\mathbb{E}[a_{i,t}^2]$ is nothing more than the expectation of the right-hand side of (3), where $\mathbb{E}[\eta_{i,t}] = 0$ for any i, t . Hence $\mathbb{E}[a_{i,t}^2] = \omega_i + \omega_i^* D_{i,t} + \sum_{k=1}^{\max\{m_i, s_i\}} (\alpha_{i,k} + \beta_{i,k}) a_{i,t-k}^2 + \gamma_i^T \mathbf{x}_{i,t}$

1. The method under development does not strictly require knowledge of the length of the shocks in the donor pool, but correctly sizing up those shock lengths is helpful to proper estimation of the shocks in the donor pool. An important question remains: even if the donor pool shock lengths are assumed to be known, how do we advise the operator to forecast the time series under study? For how long is the forecast reliable? Should we take a convex combination of the donor pool shock lengths? Or mean? Or minimum of the donor pool shock lengths?
2. [Lin and Eck \[2021\]](#) requires exogenous information to arrive strictly between T^* and T^*+1 . However, we may want to relax this requirement so as to permit the exogenous information to be concurrent with the trading session or end of session on T^*+1 .
3. See Tsay p. 133: if t is the last index that has been observed, then our two-step-ahead forecast is made easier by rewriting the volatility equation as $\sigma_{i,t+1}^2 = w_i + (\alpha_i + \beta_i)\sigma_{i,t}^2 + \alpha_1\sigma_{i,t}^2[\epsilon_{i,t}^2 - 1] = w_i + (\alpha_i + \beta_i)\sigma_{i,t}^2 + \alpha_1\sigma_{i,t}^2[\epsilon_{i,t}^2 - 1]$. Usually, we assume unit variance (though not necessarily a $N(0,1)$). However, what is the variance is smaller than 1? Then in conditional expectation, the term $\alpha_1\sigma_{i,t}^2[\epsilon_{i,t}^2 - 1]$ will be negative. So it seems that for level shock, we want the signal to noise ratio to be large because the mean is high, not because the variance is low.

3 Setting

We follow convention and define the daily log-return as $r_t = \log(\frac{P_{t+1}}{P_t})$, where P_t denotes the price at time t . The class of ARIMA(p,d,q) models developed in the mid-to-late 20th century [\[Box, 2013\]](#) provides a framework for postulating and quantifying the autoregressive structure of r_t , all within the framework of frequentist statistics. These models assume a certain dependence structure between r_t and $(r_k)_{k \leq t}$, yet their errors – often called innovations in the financial time series context due to how they represent the impact of new information – are nevertheless assumed to be i.i.d. with mean zero and constant variance. The ARCH [\[Engle, 1982\]](#) and GARCH [\[Bollerslev, 1986\]](#) models provide elegant alternatives to the constant-variance assumption. In fact, the GARCH framework in its most basic form disregards r_t and instead turns its interest to the series r_t^2 (when properly centered, i.e. after assuming a mean-model for returns).

To that end, let $a_t = r_t - \mu_t$, where μ_t is the mean of the log return series r_t . Implicitly, we are committing ourselves to a mean-model for r_t in which μ_t , the expected daily log-return, may vary with time, while a_t is simply the noise. As [Cont \[2001\]](#) explains, such an assumption is justified by the empirical finding that returns lack significant autocorrelation. We derive a mean-zero process $(a_t)_{t \in \mathbb{N}}$ with the property that $\mathbb{E}[a_t^2] = \text{Var}[a_t]$. Under the assumption of time-invariant volatility, the series a_t^2 should exhibit no autocorrelation at any lag $\ell \geq 1$. This assumption motivates tests for so-called ARCH effects, that is, tests for the clustering of volatility. These tests explore the alternative hypothesis that σ_t^2 is not only a time-varying parameter but furthermore a function of past squared residuals of the mean model. In particular, the ARCH(m) model is an autoregressive model in which σ_t^2 is fitted using a linear combination of the m past values of a_t^2 . The GARCH(m,s) framework take this one step further but modeling σ_t^2 as a linear combination of the m past a_t^2 values and well as the s past values of σ_t^2 . In functional form,

$$\sigma_t^2 = \omega + \sum_{k=1}^m \alpha_k a_{t-k}^2 + \sum_{j=1}^s \beta_j \sigma_{t-j}^2$$

$$a_t = \sigma_t \epsilon_t$$

Assuming further that σ_t^2 depends on a vector of exogenous covariates \mathbf{x}_t (a so-called ‘‘GARCH-X’’), we have

$$\sigma_t^2 = \omega + \sum_{k=1}^m \alpha_k a_{t-k}^2 + \sum_{j=1}^s \beta_j \sigma_{t-j}^2 + \gamma^T \mathbf{x}_t$$

$$a_t = \sigma_t \epsilon_t$$

We will suppose that a researcher has multivariate time series data $\mathbf{y}_{i,t}$, $t = 1, \dots, T_i$ and $i = 1, \dots, n+1$. We let $\mathbf{y}_{i,t} = (y_{i,t}, \mathbf{x}_{i,t}, \mathbf{v}_{i,t})$ where $y_{i,t}$ is a scalar response, $\mathbf{x}_{i,t}$ is a vector of covariates that are revealed to the analyst prior to the observation of $y_{1,t}$, and $\mathbf{v}_{i,t}$ is a vector of market-implied volatility metrics for the series i that are available prior to the market open at time t . Suppose that the analyst is interested in forecasting the volatility of $y_{1,t}$, the first time series in the collection. We require that each time series $\mathbf{y}_{i,t}$ is subject to a news event immediately following $T_i^* \leq T_i + 1$ and before witnessing $T_i^* + 1$.

In light of the foregoing, we can rewrite the GARCH framework we are interested in as such

$$\sigma_{i,t}^2 = \omega_i + \sum_{k=1}^{m_i} \alpha_{i,k} a_{i,t-k}^2 + \sum_{j=1}^{s_i} \beta_{i,j} \sigma_{i,t-j}^2 + \gamma_i^T \begin{pmatrix} \mathbf{x}_{i,t} \\ \mathbf{v}_{i,t} \end{pmatrix}$$

$$a_{i,t} = \sigma_{i,t} \epsilon_{i,t}$$

We are interested in a point forecast for σ_{1,T^*+h}^2 , $h = 1, 2, \dots, H$, the h -step ahead conditional variance for the time series under study, up to a forecast length of H . The forecast performance evaluation uses three distinct loss functions, each computed using three families of estimators for the ground truth that we seek. Let L^h with the subscripted pair {prediction method, ground truth estimator}, denote the loss function for an h -step-ahead forecast using a given prediction function and ground truth estimator. For example, one loss function of interest in this study is the 1-step-ahead MSE using Synthetic Volatility Forecasting and Realized Volatility:

$$MSE_{SVF,RV}^1 = (\hat{\sigma}_{SVF}^2 - \hat{\sigma}_{RV}^2)^2$$

In more generality, for an multihorizon volatility forecast with forecast length H , the loss function is

$$MSE_{method,groundtruth}^H = \frac{1}{H} \sum_{h=1}^H (\hat{\sigma}_{h,method}^2 - \hat{\sigma}_{h,groundtruth}^2)^2$$

Also of interest in mean absolute-percentage-error for an h -step-ahead forecast, defined as

$$MAPE_{method,groundtruth}^H = \frac{1}{H} \sum_{h=1}^H \frac{|\hat{\sigma}_{h,method}^2 - \hat{\sigma}_{h,groundtruth}^2|}{\hat{\sigma}_{h,groundtruth}^2}$$

Finally, we introduce the QL (quasi-likelihood) Loss [Brownlees et al., 2011]:

$$QL_{method,groundtruth}^H = \frac{1}{H} \sum_{h=1}^H \left(\frac{\hat{\sigma}_{h,method}^2}{\hat{\sigma}_{h,groundtruth}^2} - \log \frac{\hat{\sigma}_{h,method}^2}{\hat{\sigma}_{h,groundtruth}^2} - 1 \right)$$

What distinguishes QL Loss is that it is multiplicative rather than additive. This serves as a basis for some of its virtues, both practical and theoretical. As Brownlees et al. [2011] explains, ‘‘[a]mid volatility turmoil, large MSE losses will be a consequence of high volatility without necessarily corresponding to deterioration of forecasting ability. The QL avoids this ambiguity, making it easier to compare losses across volatility regimes.’’

3.1 Ground Truth Estimators

The price series of a financial asset is a sequence of observable random variables; in particular, for any t , P_t is realized at t and henceforth no longer random, under the assumption that $(P_t)_{t \in \mathbb{N}}$ is adapted to \mathcal{F}_t . Time series econometrics has a vast inventory of approaches for modeling P_t . In contrast, the time-varying parameter σ_t^2 is a quantity for which even identifying an observable effect in the real world is far more challenging. Approaches come in two basic forms: model-independent and model-dependent. The naive approach of constructing a rolling unbiased estimator of the variance of a price series is analogous to using a rolling average to estimate the mean of a price series. Implicitly, these approaches assume a simple, if unrealistic, covariance structure. Additionally, they offer very little in the way of forward guidance (predictiveness) regarding the series at hand. For that reason, in this section, we propose three families of estimators of the ground truth that we aim to forecast.

3.1.1 Market-Implied Volatility

Here we introduce implied volatility, a quantity that is derived using the equilibrium price of call and put options on the underlying financial asset.

We note also that Black-Scholes implied volatility is a biased estimator of volatility [Mayhew, 1995, Christensen and Prabhala, 1998], with the bias increasing in times of crises when options are out-of-the-money.

3.1.2 Realized Volatility

Suppose we examine K units of time, where each unit is divided into m intervals of length $1/m$. We follow the notation of Andersen and Teräsvirta [2009]. Let $p_t = \log(P_t)$, and let $r(t, 1/m) = p_t - p_{t-1/m}$. We estimate the variance of a log-return series using Realized Volatility, denoted $RV_{K,m}$, using

$$RV_{K,m} = \frac{1}{K} \sum_{v=1}^{Km} r^2(v/m, 1/m)$$

Assuming that the K units $r(t, 1) = p_t - p_{t-1}$ are such that $r(t, 1) \stackrel{iid}{\sim} N(\mu, \delta^2)$, it is easily verified that

$$\mathbb{E}[RV_{K,m}] = \frac{\mu^2}{m} + \delta^2$$

which is a biased but consistent estimator of the variance.

3.1.3 Historical Volatility

As discussed in section 2, daily returns exhibit insignificant autocorrelation. Such a finding could be used to motivate using the empirical volatility. This is just the unbiased estimator of log-return σ^2 over the preceding M days.

3.2 Volatility Profile of a Time Series

In this section we make a novel contribution to the synthetic prediction framework by constructing a profile of a time series' volatility. Suppose we have D donors and for each of those D donors, q distinct measurements and/or covariates of volatility. Abusing notation for RV (I need some clever way to index (a) date, (b) donor, (c) how many days were used to get the measurement, we have...

$$\mathbf{V}_{q,D} = \begin{pmatrix} \alpha_{T^*,1} & \alpha_{T^*,2} & \cdots & \alpha_{T^*,D} \\ \beta_{T^*,1} & \beta_{T^*,2} & \cdots & \beta_{T^*,D} \\ \vdots & \vdots & \ddots & \vdots \\ RV_{T^*,1} & RV_{T^*,2} & \cdots & RV_{T^*,D} \\ RV_{T^*-1,1} & RV_{T^*-1,2} & \cdots & RV_{T^*-1,D} \\ \vdots & \vdots & \ddots & \vdots \\ IV_{T^*,1} & IV_{T^*,2} & \cdots & IV_{T^*,D} \\ IV_{T^*-1,1} & IV_{T^*-1,2} & \cdots & IV_{T^*-1,D} \\ \vdots & \vdots & \ddots & \vdots \\ AbsoluteReturn_{T^*,1} & AbsoluteReturn_{T^*,2} & \cdots & AbsoluteReturn_{T^*,D} \\ AbsoluteReturn_{T^*-1,1} & AbsoluteReturn_{T^*-1,2} & \cdots & AbsoluteReturn_{T^*-1,D} \\ \vdots & \vdots & \ddots & \vdots \\ Volume_{T^*,1} & Volume_{T^*,2} & \cdots & Volume_{T^*,D} \\ Volume_{T^*-1,1} & Volume_{T^*-1,2} & \cdots & Volume_{T^*-1,D} \\ \vdots & \vdots & \ddots & \vdots \\ \Delta RV_{T^*,1} & \Delta RV_{T^*,2} & \cdots & \Delta RV_{T^*,D} \\ \Delta RV_{T^*-1,1} & \Delta RV_{T^*-1,2} & \cdots & \Delta RV_{T^*-1,D} \\ \vdots & \vdots & \ddots & \vdots \end{pmatrix}$$

3.3 Aggregation Mechanism

Here we explain how we use the volatility profile to arrive at a set of nonnegative weights that sum to 1. These weights are then used to compute $\hat{\omega}^* = \sum_{i=2}^{n+1} w_i \hat{\omega}_i$.

In [Abadie et al. \[2010\]](#), the authors advance previous work in causal inference whereby a treatment effect can be estimated by creating a synthetic time series that represents either the treatment or control unit. The synthetic unit is constructed using a convex combination of so-called donor series. The particular convex combination employed is a function of the distance between the time series under study and the donors. [Lin and Eck \[2021\]](#) adapt these methods for the purpose of prediction. Their 1-step-ahead forecasts take inspiration from distance-based-weighting, pooling shock estimates from similar series according to the series' similarity to the series under study. The use of fixed-effect estimation for structural shocks has a pedigree ([Romer and Romer \[1989\]](#) cited in [Kilian and Lütkepohl \[2017\]](#)). Their approach does not take into account the ARCH effects commonly observed in time series, especially financial times series, leaving unaccounted the variability that accompanies predictions of a heteroskedastic time series. In this present study, we focus on only volatility forecasting. We furthermore depart from the synthetic prediction framework by weighting series not by their covariates (which would be most appropriate for estimating the parameters of time series' mean model) but by their volatility profile.

3.4 Model setup

In this section, we will describe the assumed dynamic panel models for which post-shock aggregated estimators are provided. The basic structures of these models are the same for all time series in the analysis, the differences between them lie in the setup of the shock effect distribution. We first sharply distinguish between a volatility shock induced by a return series shock and a volatility shock directly affecting the volatility equation of a GARCH model, without mediation of the return series.

3.4.1 Mean Model and Volatility Model

Let $I(\cdot)$ be an indicator function, T_i be the time length of the time series i for $i = 1, \dots, n+1$, and T_i^* denote the largest time index prior to the arrival of the news shock, with $T_i^* < T_i$. For $t = 1, \dots, T_i$ and $i = 1, \dots, n+1$, the model \mathcal{M}_1 is defined as

$$\mathcal{M}_1: \sigma_{i,t}^2 = \omega_i + \omega_i^* D_{i,t}^{vol} + \sum_{k=1}^{m_i} \alpha_{i,k} a_{i,t-k}^2 + \sum_{j=1}^{s_i} \beta_{i,j} \sigma_{i,t-j}^2 + \gamma_i^T \mathbf{x}_{i,t} \quad (4)$$

$$a_{i,t} = \sigma_{i,t}(\epsilon_{i,t}(1 - D_{i,t}^{level}) + \epsilon_i^* D_{i,t}^{level}) \quad (5)$$

$$\omega_i^* = \mu_{\omega^*} + \varepsilon_i \quad (6)$$

where $D_{i,t}^{vol} = I(t \in \{T_i^* + 1, \dots, T_i^* + L_{i,vol}\})$, $D_{i,t}^{level} = I(t \in \{T_i^* + 1, \dots, T_i^* + L_{i,level}\})$ and $\mathbf{x}_{i,t} \in \mathbb{R}^p$, with $p \geq 1$. We assume that the $\mathbf{x}_{i,t}$ are fixed^{1,23}. For $i = 1, \dots, n+1$ and $t = 1, \dots, T_i$, the random effects structure for \mathcal{M}_1 is:

$$\begin{aligned} \omega_i^* &\stackrel{iid}{\sim} \mathcal{F}_{\omega^*} \text{ with } \mathbb{E}_{\mathcal{F}_{\omega^*}}(\omega_i^*) = \mu_{\omega^*}, \text{Var}_{\mathcal{F}_{\omega^*}}(\omega_i^*) = \sigma_{\omega^*}^2 \\ \epsilon_{i,t} &\stackrel{iid}{\sim} \mathcal{F}_{\epsilon} \text{ with } \mathbb{E}_{\mathcal{F}_{\epsilon}}(\epsilon) = 0, \text{Var}_{\mathcal{F}_{\epsilon}}(\epsilon) = \sigma_{\epsilon}^2 \\ \epsilon_{i,t}^* &\stackrel{iid}{\sim} \mathcal{F}_{\epsilon^*} \text{ with } \mathbb{E}_{\mathcal{F}_{\epsilon^*}}(\epsilon_{i,t}^*) = \mu_{\epsilon^*}, \text{Var}_{\mathcal{F}_{\epsilon^*}}(\epsilon_{i,t}^*) = \sigma_{\epsilon^*}^2 \\ \varepsilon_{i,t} &\stackrel{iid}{\sim} \mathcal{F}_{\varepsilon} \text{ with } \mathbb{E}_{\mathcal{F}_{\varepsilon}}(\varepsilon_{i,t}) = 0, \text{Var}_{\mathcal{F}_{\varepsilon}}(\varepsilon_{i,t}) = \sigma_{\varepsilon}^2 \\ \omega_i^* &\perp\!\!\!\perp \epsilon_{i,t} \perp\!\!\!\perp \epsilon_{i,t}^* \perp\!\!\!\perp \varepsilon_{i,t}. \end{aligned}$$

Notice that \mathcal{M}_1 assumes that ω_i^* are i.i.d. with $\mathbb{E}[\omega_i^*] = \mu_{\omega^*}$ for $i = 1, \dots, n+1$. We also consider a model where the shock effects are linear functions of covariates with an additional additive mean-zero error. For $i = 1, \dots, n+1$, the random effects structure for this model (model \mathcal{M}_2) is:

$$\begin{aligned} \mathcal{M}_2: \sigma_{i,t}^2 &= \omega_i + \omega_i^* D_{i,t}^{vol} + \sum_{k=1}^{m_i} \alpha_{i,k} a_{i,t-k}^2 + \sum_{j=1}^{s_i} \beta_{i,j} \sigma_{i,t-j}^2 + \gamma_i^T \mathbf{x}_{i,t} \\ a_{i,t} &= \sigma_{i,t}(\epsilon_{i,t}(1 - D_{i,t}^{level}) + \epsilon_i^* D_{i,t}^{level}) \\ \omega_i^* &= \mu_{\omega^*} + \delta' \mathbf{x}_{i,T_i^*} + \varepsilon_i, \end{aligned}$$

with random effects structure

$$\begin{aligned} \omega_i^* &\stackrel{iid}{\sim} \mathcal{F}_{\omega^*} \text{ with } \mathbb{E}_{\mathcal{F}_{\omega^*}}(\omega_i^*) = \mu_{\omega^*}, \text{Var}_{\mathcal{F}_{\omega^*}}(\omega_i^*) = \sigma_{\omega^*}^2 \\ \epsilon_{i,t} &\stackrel{iid}{\sim} \mathcal{F}_{\epsilon} \text{ with } \mathbb{E}_{\mathcal{F}_{\epsilon}}(\epsilon) = 0, \text{Var}_{\mathcal{F}_{\epsilon}}(\epsilon) = \sigma_{\epsilon}^2 \\ \epsilon_{i,t}^* &\stackrel{iid}{\sim} \mathcal{F}_{\epsilon^*} \text{ with } \mathbb{E}_{\mathcal{F}_{\epsilon^*}}(\epsilon_{i,t}^*) = \mu_{\epsilon^*}, \text{Var}_{\mathcal{F}_{\epsilon^*}}(\epsilon_{i,t}^*) = \sigma_{\epsilon^*}^2 \\ \delta &\stackrel{iid}{\sim} \mathcal{F}_{\delta} \text{ with } \mathbb{E}_{\mathcal{F}_{\delta}}(\delta) = \mu_{\delta}, \text{Var}_{\mathcal{F}_{\delta}}(\delta) = \Sigma_{\delta} \\ \varepsilon_{i,t} &\stackrel{iid}{\sim} \mathcal{F}_{\varepsilon} \text{ with } \mathbb{E}_{\mathcal{F}_{\varepsilon}}(\varepsilon_{i,t}) = 0, \text{Var}_{\mathcal{F}_{\varepsilon}}(\varepsilon_{i,t}) = \sigma_{\varepsilon}^2 \\ \omega_i^* &\perp\!\!\!\perp \epsilon_{i,t} \perp\!\!\!\perp \epsilon_{i,t}^* \perp\!\!\!\perp \delta \perp\!\!\!\perp \varepsilon_{i,t} \end{aligned}$$

¹Is this necessary? Does it serve a purpose?

²Need to determine what difference it makes to a GARCH-X model, if any, for the covariates to be random.

³As for implied volatility as a covariate, the argument for regarding it as a non-random quantity is that we are not primarily concerned with what IV is trying to estimate. We're concerned with IV itself at a primitive quantity that affects volatility through market sentiment.

We further define the parameter sets

$$\begin{aligned}\Theta &= \{(\omega_i^*, \epsilon_{i,t}, \epsilon_{i,t}^*, \delta, \varepsilon_{i,t}) : t = 1, \dots, T_i, i = 2, \dots, n+1\}, \\ \Theta_1 &= \{(\omega_i^*, \epsilon_{i,t}, \epsilon_{i,t}^*, \varepsilon_{i,t}) : t = 1, \dots, T_i, i = 2, \dots, n+1\},\end{aligned}\tag{7}$$

where Θ and Θ_1 can be adapted to \mathcal{M}_1 by dropping δ . We assume this for notational simplicity.

3.5 Properties of Volatility Shock and Shock Estimators

The model \mathcal{M}_1 is defined by a volatility equation and mean equation, as is any GARCH model. The choice to model the volatility shock ω_i^* as an additive random effect is straightforward. However, the choice to model the level effect $\epsilon_{i,t}^*$ as a temporary rupture in the otherwise i.i.d. sequence of innovations $\epsilon_{i,t}$ stands in need of deeper justification. One way of arguing for this choice is that, in a discrete time series model, if we assume the arrival of news in the time between T^* and $T^* + 1$, we do not have an easy way to express a conditional distribution of the innovation ϵ_{T^*+1} given the overnight arrival of information. Using $\epsilon_{i,t}^*$ thus breaks this impasse. This defense also explains why we do not parameterize the level shock at $T^* + 1$ as a sum of two shocks, ϵ_{i,T^*+1} and ϵ_{i,T^*+1}^* , which would represent the level shock as generated by two independent sources of stochasticity. To do so would be inelegant and would also lack motivation as a practical level. While we want to model the shock at $T^* + 1$ as large in absolute value, we also want to retain the property of a unitary source of noise.

Note that under the popular GARCH(1,1), a dual level-volatility shock has an marginal effect on the conditional variance $\sigma_{i,t}^2$ that should be familiar to scholars of GARCH models. As usual, assume $\alpha + \beta < 1$. Furthermore, assume that both the volatility shock ω_i^* and the level shock $\epsilon_{i,t}^*$ are of length one only, and consider a circumstance with no exogenous regressor $\mathbf{x}_{i,t}$. Consider also the case where $r \geq 2$, which is necessary in order to isolate the effects of the level shock $\epsilon_{i,t}^*$. Then

$$\sigma_{i,T^*+r+1}^2 = \omega_i + \alpha_i a_{T^*+r}^2 + \beta_i \sigma_{i,T^*+r}^2 \tag{8}$$

$$= \omega_i + \alpha_i (\sigma_{i,T^*+r} \epsilon_{T^*+r})^2 + \beta_i \sigma_{i,T^*+r}^2 \tag{9}$$

$$= \omega_i + \sigma_{i,T^*+r}^2 (\alpha_i (\epsilon_{T^*+r})^2 + \beta_i) \tag{10}$$

In (8), observe that ω_i^* and $\epsilon_{i,t}^*$ each appear at most once, through the term σ_{i,T^*+r}^2 . This might lead one to suspect geometric decay of the shocks ω_i^* and $\epsilon_{i,t}^*$. Such a suspicion is easier to substantiate by examining the conditional expectation of the variance, $\mathbb{E}[\sigma_{i,T^*+r+1}^2 | \mathcal{F}_{T^*+r}]$, which also happens to be the principal forecasting tool for a GARCH model [Zivot, 2009]. Indeed, if we assume unit variance for all $\epsilon_{i,t}$ except, of course, $\epsilon_{i,t}^*$, then we have

$$\begin{aligned}\mathbb{E}[\sigma_{i,T^*+r+1}^2 | \mathcal{F}_{T^*+r}] &= \mathbb{E}[\omega_i + \alpha a_{T^*+r}^2 + \beta \sigma_{i,T^*+r}^2 | \mathcal{F}_{T^*+r}] \\ &= \omega_i + \mathbb{E}[\alpha (\sigma_{i,T^*+r} \epsilon_{T^*+r})^2 | \mathcal{F}_{T^*+r}] + \beta \sigma_{i,T^*+r}^2 \\ &= \omega_i + \alpha \sigma_{i,T^*+r}^2 + \beta \sigma_{i,T^*+r}^2 \quad (\text{Due to the unit variance assumption}) \\ &= \omega_i + \sigma_{i,T^*+r}^2 (\alpha + \beta)\end{aligned}$$

By repeated substitution, in conditional expectation, the shock is $\mathcal{O}((\alpha + \beta)^r)$. We generalize this observation in the following proposition.

Proposition 1. *Let a_t be a mean-zero time series obeying a GARCH(1,1) specification with unit-variance errors, all prior to the arrival of a volatility shock of length $L_{vol} \geq 1$ and level shock of length $L_{level} \geq 1$ at some time $T^* + 1$. Then for any r such that $r \geq \max\{L_{i,vol}, L_{i,level}\} + 1$,*

$$\mathbb{E}[\sigma_{i,T^*+r+1}^2 | \mathcal{F}_{T^*+r}] = \omega_i + \sigma_{i,T^*+r}^2(\alpha + \beta) \quad (11)$$

$$(12)$$

Proof of Proposition We claim

$$\mathbb{E}[\sigma_{i,T^*+r+1}^2 | \mathcal{F}_{T^*+r}] = \mathbb{E}[\omega_i + \alpha a_{i,T^*+r}^2 + \beta \sigma_{i,T^*+r}^2 | \mathcal{F}_{T^*+r}] \quad (13)$$

$$= \omega_i + \mathbb{E}[\alpha (\sigma_{i,T^*+r} \epsilon_{i,T^*+r})^2 | \mathcal{F}_{T^*+r}] + \beta \sigma_{i,T^*+r}^2 \quad (14)$$

$$= \omega_i + \alpha \sigma_{i,T^*+r}^2 + \beta \sigma_{i,T^*+r}^2 \quad (15)$$

$$= \omega_i + \sigma_{i,T^*+r}^2(\alpha + \beta) \quad (16)$$

The volatility equation of a GARCH(1,1) dictates that for any r , the one-step-ahead volatility is given by the expression inside the expectation in (13). By the mean-model assumption of a GARCH(1,1), we have $a_{i,t} = \sigma_{i,t} \epsilon_{i,t}$ and hence by substituting $\sigma_{i,t} \epsilon_{i,t}$ for $a_{i,t}$, we arrive at equation (14) above. Using the unit-variance assumption regarding ϵ_{T^*+r} , we can compute explicitly the expectation in (15). Finally, by rearranging terms, we arrive at equation (16). \square

In other words, for a GARCH(1,1), once two time points removed from the longest shock length, the volatility shock and level shock can be subsumed into one. However, prior to being two time points removed, there is no such guarantee. For example, one can take $r = 1$ and level shock of length at least one to see that

$$\mathbb{E}[\sigma_{i,T^*+r+1}^2 | \mathcal{F}_{T^*+r}] = \mathbb{E}[\omega_i + \alpha a_{i,T^*+1}^2 + \beta \sigma_{i,T^*+1}^2 | \mathcal{F}_{T^*+1}] \quad (17)$$

$$= \omega_i + \mathbb{E}[\alpha (\sigma_{i,T^*+1} \epsilon_{i,T^*+1}^*)^2 | \mathcal{F}_{T^*+1}] + \beta \sigma_{i,T^*+1}^2 \quad (18)$$

$$= \omega_i + \alpha \sigma_{i,T^*+1}^2 (\mu_{\epsilon^*}^2 + \sigma_{\epsilon^*}^2) + \beta \sigma_{i,T^*+1}^2 \quad (19)$$

$$= \omega_i + \sigma_{i,T^*+1}^2 (\alpha (\mu_{\epsilon^*}^2 + \sigma_{\epsilon^*}^2) + \beta) \quad (20)$$

For each of the p entries in δ , the k th entry should have the property that

$$\mathbb{E}[x_{i,t,k} \cdot \delta_k] > 0$$

In principle, you could have an \mathcal{M}_{21} shock with a covariate that, in expectation, has a negative marginal contribution to the cumulative shock.

Moreover, after both shocks have been exhausted, their influence disappears quickly. This short-memory effect has implications for the method being developed herein:

1. Estimation of effects in donor pool should err on the side of underestimating, not overestimating, the length of the max shock, since overestimation of the shock length brings with it the risk of underestimating ω^* .
2. An operator of the method needs some idea of how long the operator expects the shock in the time series under study to be. Such an idea will guide her trust in the choice of k in the k -step ahead forecast the operator produces. There are couple of obvious strategies: take all the donors, and over all the donor shock lengths, take the minimum. Alternatively, one could take the maximum.
3. There may be different risks associated with over/underestimating level shock and vol shock lengths.

In many settings, it is reasonable to model a volatility shock as occurring without a rupture in the mean-zero, i.i.d. sequence $\epsilon_{i,t}$. In cases like this, outsize movement in the observable random variable $a_{i,t}$ is due solely to the shock ω_i^* . Using the ARMA representation of a GARCH(m,s) model, we can see clearly how the random effect ω_i^* increases the expectation of the nonnegative random variable $a_{i,t}^2$. The unconditional mean of an ARMA model tells that the random effects simply contribute to the intercept term (see Tsay p. 132):

$$\mathbb{E}[a_{i,t}^2] = \frac{\omega_i + \mathbb{E}[\omega_i^*]}{1 - \sum_{k=1}^{\max(m,s)} (\alpha_{i,k} + \beta_{i,k})}$$

However, since it is not known a priori for which t the effect ω_i^* will be nonzero, this fact is of little practical guidance.

3.6 Unbiasedness of the Synthetic Volatility fixed-effect estimators and Synthetic Volatility prediction functions

Recall models \mathcal{M}_1 and \mathcal{M}_2 :

$$\begin{aligned}\mathcal{M}_1: \sigma_{i,t}^2 &= \omega_i + \omega_i^* D_{i,t}^{vol} + \sum_{k=1}^{m_i} \alpha_{i,k} a_{i,t-k}^2 + \sum_{j=1}^{s_i} \beta_{i,j} \sigma_{i,t-j}^2 + \gamma_i^T \mathbf{x}_{i,t} \\ a_{i,t} &= \sigma_{i,t} (\epsilon_{i,t} (1 - D_{i,t}^{level}) + \epsilon_i^* D_{i,t}^{level}) \\ \omega_i^* &= \mu_{\omega^*} + \varepsilon_i\end{aligned}$$

$$\begin{aligned}\mathcal{M}_2: \sigma_{i,t}^2 &= \omega_i + \omega_i^* D_{i,t}^{vol} + \sum_{k=1}^{m_i} \alpha_{i,k} a_{i,t-k}^2 + \sum_{j=1}^{s_i} \beta_{i,j} \sigma_{i,t-j}^2 + \gamma_i^T \mathbf{x}_{i,t} \\ a_{i,t} &= \sigma_{i,t} (\epsilon_{i,t} (1 - D_{i,t}^{level}) + \epsilon_i^* D_{i,t}^{level}) \\ \omega_i^* &= \mu_{\omega^*} + \delta' \mathbf{x}_{i,T_i^*} + \varepsilon_i,\end{aligned}$$

We will discuss these two models in the context of a shock in only the volatility, i.e. with $D_{i,t}^{level} \equiv 0$.

Abadie et al. [2010] discuss the unbiasedness of SCM estimators in the context of an autoregressive model. It is well-known that a GARCH(m,s) model has an ARMA representation. This suggests that, at the very least, when applied to an autoregressive process such as an ARCH model, Synthetic Volatility Forecasting provides an unbiased prediction. We therefore set out to show three results of increasing difficulty and complexity.

Proposition 2. *Under \mathcal{M}_1 and \mathcal{M}_2 , if the volatility series follows an ARCH(1) model, then under the assumptions in Abadie et al. [2010], $\hat{\omega}^*$ is an unbiased estimator of $\mathbb{E}[\omega_1^*]$.*

Proof of Proposition First, for each i, t , define $\eta_{i,t} := a_{i,t}^2 - \sigma_{i,t}^2$, and by adding $\eta_{i,t}$ to both sides of the conditional variance specification of \mathcal{M}_1 and \mathcal{M}_2 , we obtain the standard ARMA representation of a GARCH(m,s):

$$\begin{aligned}a_{i,t}^2 &= a_{i,t}^2 - \sigma_{i,t}^2 + \sigma_{i,t}^2 = \eta_{i,t} + \sigma_{i,t}^2 = \eta_{i,t} + \omega_i + \omega_i^* D_{i,t} + \sum_{k=1}^{m_i} \alpha_{i,k} a_{i,t-k}^2 + \sum_{j=1}^{s_i} \beta_{i,j} \sigma_{i,t-j}^2 + \gamma_i^T \mathbf{x}_{i,t} \\ &= \eta_{i,t} + \omega_i + \omega_i^* D_{i,t} + \sum_{k=1}^{m_i} \alpha_{i,k} a_{i,t-k}^2 + \sum_{j=1}^{s_i} \beta_{i,j} (a_{i,t-j}^2 - \eta_{i,t-j}) + \gamma_i^T \mathbf{x}_{i,t}\end{aligned}$$

$$= \eta_{i,t} + \omega_i + \omega_i^* D_{i,t} + \sum_{k=1}^{\max\{m_i, s_i\}} (\alpha_{i,k} + \beta_{i,k}) a_{i,t-k}^2 - \sum_{j=1}^{s_i} \beta_{i,j} \eta_{i,t-j} + \gamma_i^T \mathbf{x}_{i,t}$$

where the $a_{i,t}^2$ (the autoregressive terms) are observable and the $\eta_{i,t}$ (the moving average terms) are not. Next, as shown in [Abadie et al. \[2010\]](#), under the autoregressive model

$$\begin{aligned} y_{i,t} &= \alpha_{i,t-1} y_{i,t-1} + \beta_t \mathbf{X}_{i,t} + u_{i,t} \\ \mathbf{X}_{i,t} &= \gamma_{t-1} y_{i,t-1} + \boldsymbol{\Pi}_{t-1} \mathbf{X}_{i,t-1} + \mathbf{v}_{i,t} \end{aligned}$$

and the assumptions that we, the practitioner, choose $\{w_i^*\}_{2 \leq i \leq n+1}$ such that

$$\sum_{i=2}^{n+1} w_i^* Y_{i,T^*} = Y_1^* \quad \text{and} \quad \sum_{i=2}^{n+1} w_i^* \mathbf{X}_{i,T^*} = \mathbf{X}_{1,T^*}^*$$

and $u_{i,t}, \mathbf{v}_{i,t}$ are mean-zero conditional of $\mathcal{F}_t = \{Y_{i,t}, \mathbf{X}_{i,t}\}_{i=2}^{n+1}$.

then with even just one pre-treatment period, the synthetic control estimator is unbiased. Applying this result to Synthetic Volatility Forecasting, assume we choose $\{w_i^*\}_{2 \leq i \leq n+1}$ such that

$$\sum_{i=2}^{n+1} w_i^* a_{i,T^*}^2 = a_{1,T^*}^2 \quad \text{and} \quad \sum_{i=2}^{n+1} w_i^* \mathbf{X}_{i,T^*} = \mathbf{X}_{1,T^*}^*$$

Assume further that $\omega_i \equiv 0$ in \mathcal{M}_1 and \mathcal{M}_2 . Then it follows immediately that under the ARCH(1) model with time-varying parameters, i.e. under the model

$$\begin{aligned} a_{i,t}^2 &= \alpha_{i,t-1} a_{i,t-1}^2 + \beta_t \mathbf{X}_{i,t} + u_{i,t} \\ \mathbf{X}_{i,t} &= \gamma_{t-1} a_{i,t-1}^2 + \boldsymbol{\Pi}_{t-1} \mathbf{X}_{i,t-1} + \mathbf{v}_{i,t} \end{aligned}$$

$\sum_{i=2}^{n+1} w_i^* a_{i,T^*+1}^2 - a_{1,T^*+1}^2$ is an unbiased estimator of the news shock. By inverting the ARMA representation of GARCH(m,s) above, we could recover an unbiased estimator of the news shock $\sum_{i=2}^{n+1} w_i^* \sigma_{i,T^*+1}^2 - \sigma_{1,T^*+1}^2$ if we could observe the terms $\sigma_{i,t}^2$ or estimate them without bias. In practice, we do neither. In particular, we do not observe a_{1,T^*+1}^2 until it is too late, and hence Synthetic Volatility Forecasting approaches the problem from the opposite direction: estimating $\omega_1^* = \sum_{i=2}^{n+1} w_i^* \sigma_{i,T^*+1}^2 - \sigma_{1,T^*+1}^2$ in order to estimate σ_{1,T^*+1}^2 . To this end, consider

$$\begin{aligned} a_{i,t}^2 &= \alpha_{i,t-1} a_{i,t-1}^2 + \beta_t \mathbf{X}_{i,t} + u_{i,t} \\ \mathbf{X}_{i,t} &= \mathbf{v}_{i,t} \\ \beta_t &\equiv 0, \forall t \neq T^* \\ \beta_t &= \delta, t = T^* \end{aligned}$$

Observe then that ω_i^* , as defined in \mathcal{M}_1 and \mathcal{M}_2 , is subsumed within the model above, where the μ_{ω^*} term in $\mu_{\omega^*} + \delta' \mathbf{x}_{i,T^*+1} + \tilde{\varepsilon}_i$ can be accounted for in the first entry of \mathbf{X}_{i,T^*+1} and δ without loss of generality. Since each ω_i^* is a function of \mathbf{X}_{i,T^*} and a mean-zero noise term,

□

	$\Sigma_\delta = I_p$	$\Sigma_\delta \neq I_p$
$\Sigma_{x_i, T^*} = I_p$	Easiest to model	Captures reasonable possibility of non-zero correlation in random effects
$\Sigma_{x_i, T^*} \neq I_p$	Captures empirically-verified phenomenon of non-zero correlation in covariates	Implausibly complicated to model

Proposition 3. *Under \mathcal{M}_1 and \mathcal{M}_2 , if the volatility series follows an $ARCH(p)$ model, then under the assumptions in [Abadie et al. \[2010\]](#), $\hat{\omega}^*$ is an unbiased estimator of $\mathbb{E}[\omega_1^*]$.*

Proof of Proposition Place here

□

Proposition 4. *Under \mathcal{M}_1 and \mathcal{M}_2 , if the volatility series follows an $GARCH(m, s)$ model, then under the assumptions in [Abadie et al. \[2010\]](#), $\hat{\omega}^*$ is an unbiased estimator of $\mathbb{E}[\omega_1^*]$.*

Proof of Proposition Place here

□

3.7 Consistency of the Synthetic Volatility fixed-effect estimators

Assume

1. $\forall i, \{a_{i,t}\}_{t=1, \dots, T_i}$ obeys a $GARCH(m, s)$ process, where T_i is the length of the i th series.
2. $\forall i, \{D_{i,t}^{vol}\}_{t=1, \dots, T_i}$, supported on $\{0, 1\}^{T_i}$ is exactly 1 at the shock times $\{T_i^* + 1, \dots, T_i^* + k\}$ and exactly zero otherwise.
3. Let conditions Assumption 1 of [Han and Kristensen \[2014\]](#) prevail.

Then $\hat{\omega}_i^* \xrightarrow{p} \mathbb{E}[\omega_i^*]$

Proof of Proposition Place here

□

3.8 Consistency of the Synthetic Volatility prediction function

Here we use the result above to show that $\hat{\sigma}_{1, T^*+1}^2 \xrightarrow{p} \sigma_{1, T^*+1}^2$.

3.9 Why not parameterize the volatility shock as a change in coefficients?

1. Swamped by shock: If the goal is near-term forecasting, then we don't really care how those coefficients may be changing. The assumption is that if any changes occur, their influence cannot account for the large shock. Given that the GARCH parameters for a stationary GARCH process must sum to less than 1, there is an upper bound to the forecastable change.
2. Practically infeasible: If we did that, we would need quite a few time points to reliably estimate the change in the GARCH parameters. We don't have that.

3.10 Forecasting

Here we make reference to Tsay p. 133 and explain, very similarly to Tsay, that the prediction function for a GARCH(m,s) is very similar to an ARMA prediction function. Modeled after section 2.2 here <https://arxiv.org/pdf/2008.11756.pdf>

OR we could cite Zivot [2009]

$$\mathbb{E}[\sigma_{i,T^*+r+1}^2 | \mathcal{F}_{T^*+r}]$$

4 Numerical Examples

Having introduced the model parameters above, we introduce estimation techniques that can be varied

4.1 Modeling Setup

4.2 Performance Metrics

4.3 Most elementary simulation setup

4.4 Monte Carlo results

Recall \mathcal{M}_2 :

$$\begin{aligned} \sigma_{i,t}^2 &= \omega_i + \omega_i^* D_{i,t}^{vol} + \sum_{k=1}^{m_i} \alpha_{i,k} a_{i,t-k}^2 + \sum_{j=1}^{s_i} \beta_{i,j} \sigma_{i,t-j}^2 + \gamma_i^T \mathbf{x}_{i,t} \\ \mathcal{M}_2: \quad a_{i,t} &= \sigma_{i,t}(\epsilon_{i,t}(1 - D_{i,t}^{level}) + \epsilon_i^* D_{i,t}^{level}) \\ \omega_i^* &= \mu_{\omega^*} + \delta' \mathbf{x}_{i,T_i^*} + \varepsilon_i, \end{aligned}$$

4.4.1 Most elementary simulation setup

In order to investigate the Synthetic Volatility Forecasting method

As we see in 3, when only two parameters are varied, the shock signal and the shock noise, we observe several encouraging phenomena:

- For nearly any row selected in the grid, a pronounced downward trend in the outperformance rate of the SVF exists.
- For any column selected, an increasing trend exists as the shock signal increases.
- For almost all small values of the shock signal, the outperformance rate hovers around .5, supporting the hypothesis that in the absence of a signal, any level of noise renders the method anemic.

We also introduce simulation parameters that can be varied but are not random effects

1. Length of the volatility shock
2. Length of the level shock

4.4.2 Dual shock: both a level and volatility shock at $T^* + 1$

Hypothesis: Method should do less well under level shock.

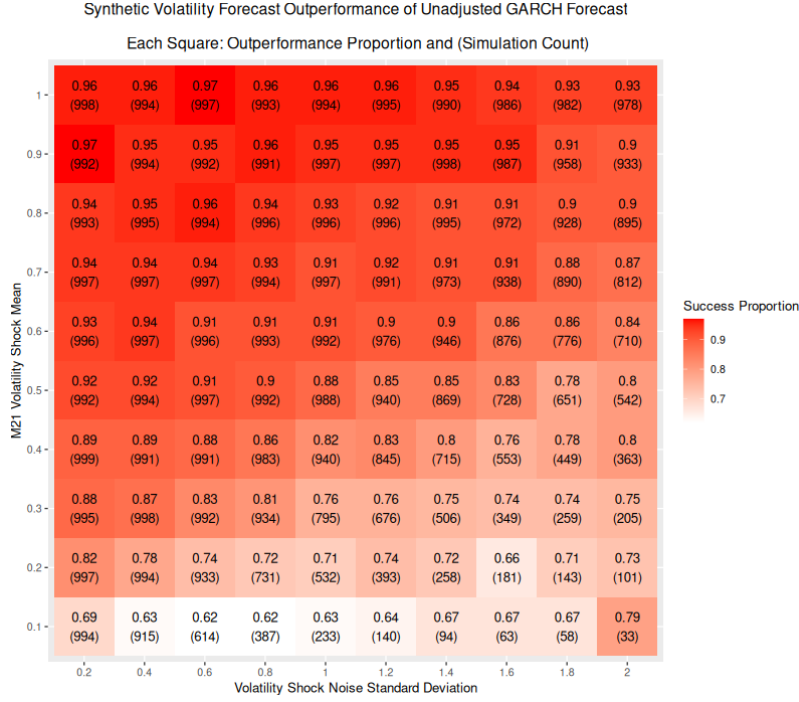

Figure 2: Fixed parameter values: $\alpha = .1, \beta = .82, \mu_x = 1, \sigma_x = .1$ (verify)

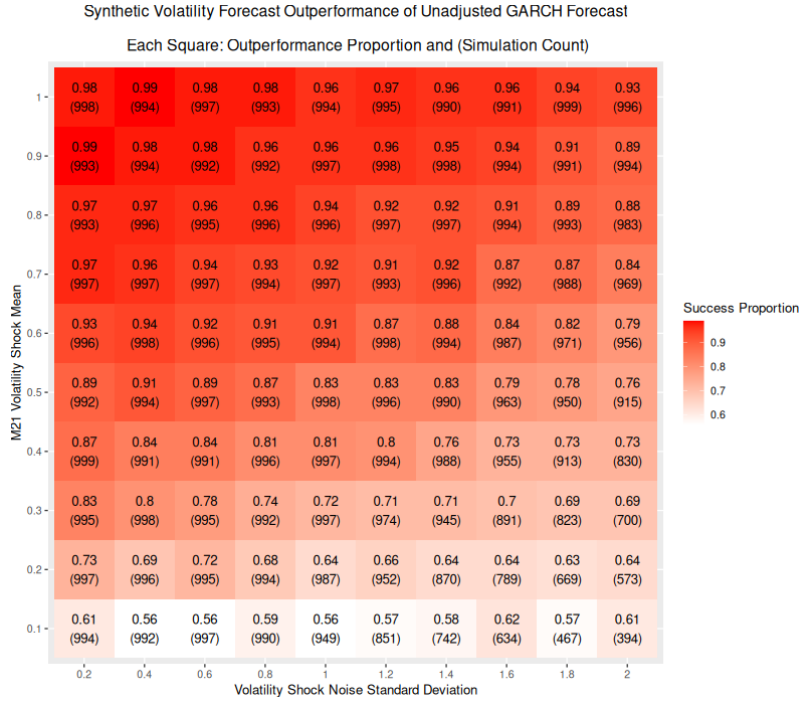

Figure 3: Fixed parameter values: $\alpha = .82, \beta = .1, \mu_x = 1, \sigma_x = .1$ (verify)

Figure 4: Dual shock: both a level and volatility shock at $T^* + 1$

4.4.3 Shorter Series

4.4.4 Fat tails in innovations

4.4.5 Lengthening the measurement period

4.4.6 Changing the optimization norm for distance-based weighting

4.4.7 Asymmetric GARCH

5 Real Data Example

We show the applicability of Synthetic Volatility Forecasting using a real data example that sits at the crossroads of financial trading and electoral politics. In the spring of 2016 in the United States, the Republican Party’s primary election process narrowed down candidates until Donald J. Trump cleared the threshold of votes to win the nomination formally at the party’s convention that summer. He would go on to face the Democratic Party’s nominee, Hillary Rodham Clinton.

From an ex-ante perspective, several qualities of the 2016 US election cycle as well as the candidates themselves made the election difficult to prognosticate. The Electoral College permits victory without a majority or even plurality of the popular vote, which can render presidential races more competitive than a raw vote total would, elevating the uncertainty surrounding the country’s future leadership. The election featured no incumbent, ruling out any incumbent-advantage of the empirical, ”statistical” kind distinguished by [Mayhew \[2008\]](#). The Republican Party candidate espoused unorthodox, populist positions on matters such as healthcare, trade, and foreign policy, some of which could be considered rare in either of the major two parties. Note here that [Goodell and Vähämaa \[2013\]](#) found support for the theory that the polling-implied probabilities of election outcomes encode information about future macroeconomic conditions, which is itself reflected in market volatility. Additionally, Donald J. Trump, lacking any record in government service – either electoral or appointed service – possessed no voting record for voters to judge or his opponents to attack.

In its final post before the election result, acclaimed forecasting outlet 538, headed by economist

Nate Silver, predicted a Clinton victory with a probability of .714, more than 2-to-1 odds [Silver, 2016], suggesting that Trump’s victory was at least somewhat surprising. For these reasons, the aftermath of the 2016 presidential election meets the standard of an interesting and notable event for which a quantitative researcher might seek a volatility point prediction. On a more technical level, the election outcome was not known until the evening of election day, well after the closing of financial markets at 4pm Eastern Time. This satisfies the condition that the shock be not yet digested by liquid markets. We therefore proceed to make the following technical specifications in order to predict the volatility of financial services ETF IYG⁴ (an ETF composed of American financial majors JPMorgan, Bank of American, etcetera) on Wednesday November 9th, 2016.

1. **Model choice** We assume a GARCH(1,1) for the daily log-return series of IYG in each donor. As argued in Hansen and Lunde [2005], a GARCH(1,1) is rarely dominated by more heavily-parameterized GARCH specifications. It thus provides a defensible choice when motivation or time for choosing another model is lacking. For the time series under study and the donor series alike, we fit a GARCH(1,1) on almost four years of market data prior to the shock.
2. **Covariate Choice** We choose covariates that could plausibly satisfy the model assumptions spelled out earlier, that is, risk-related and macroeconomic covariates that could plausibly be weighted and summed in a shock distribution. We thus choose the log-return Crude Oil (CL.F), the VIX (VIX) and the log-return of the VIX, the log-returns of the 3-month, 5-year, 10-year, and 30-year US Treasuries, as well as the log-return of the spread between AAA and BAA corporate debt, widely considered a proxy for lending risk [Goodell and Vähämaa, 2013, Kane et al., 1996]. We also include the log-return in the trading volume of the ETF IYG itself, which serves as a proxy for panic. Finally, we include the log-return in British Pound futures (6B=F), partly because we are using Brexit as a donor and partly as a proxy for US dollar strength and investor sentiment.
3. **Donor pool construction** Synthetic Control, an a tool of causal inference, often goes about weighting control units by first identifying a natural or set of donors or standard donors such as the untreated units within a set of subnational units like US states or Spanish provinces [Abadie and Gardeazabal, 2003, Abadie et al., 2010]. While such a procedure does not necessarily preclude considered judgments (should Canadian provinces be used as donors for a treated US state?), as a tool of small-n prediction, distanced-based weighting faces a decidedly more difficult task in constructing a donor pool.

For our purposes, we choose the three most recent US presidential elections prior to the 2016 election as well as the Brexit referendum held in the United Kingdom in May 2016. The three US presidential elections are the only presidential elections since the advent of the ETF IYG. We exclude the midterm congressional elections in the US (i.e. those held in even years not divisible by four), which generate far lower voter turnout and feature no national races. The inclusion of Brexit stands in need of deeper justification because it is non-standard, in the terminology introduced above. Brexit shares with the 2016 presidential race the elements of novel, unorthodox, populist, quasi-isolationist movements in an Anglophone country with a well-developed financial services sector and increasing social division: urban versus rural, colleged-education versus not, cosmopolitan versus versus localist. Although Euroskepticism and questions of the UK’s relationship with continental Europe have a long history in the UK, referenda are not common in British political decision-making, generating uncertainty about the ultimate outcome and its full consequences. Note that the constituent companies of the IYG, all of which had operations in London, were greatly exposed to the UK’s decision to remain or exit the EU. This explains how an event outside the US financial system can nevertheless be leveraged to study and predict outcomes inside the US.

⁴It has been noted that GARCH effects are more attenuated in aggregated returns [Zivot, 2009], which suggests against using the S&P 500 or similar indices as an example.

4. **Choice of estimator for volatility** We use the sum of squared 5-minute log-returns of IYG on November 9th, 2016, otherwise known as the Realized Volatility estimator of volatility [Andersen and Teräsvirta, 2009], as our proxy. We exclude the first five minutes of the trading day, resulting in 77 sums generated between 9:35am and 4pm.

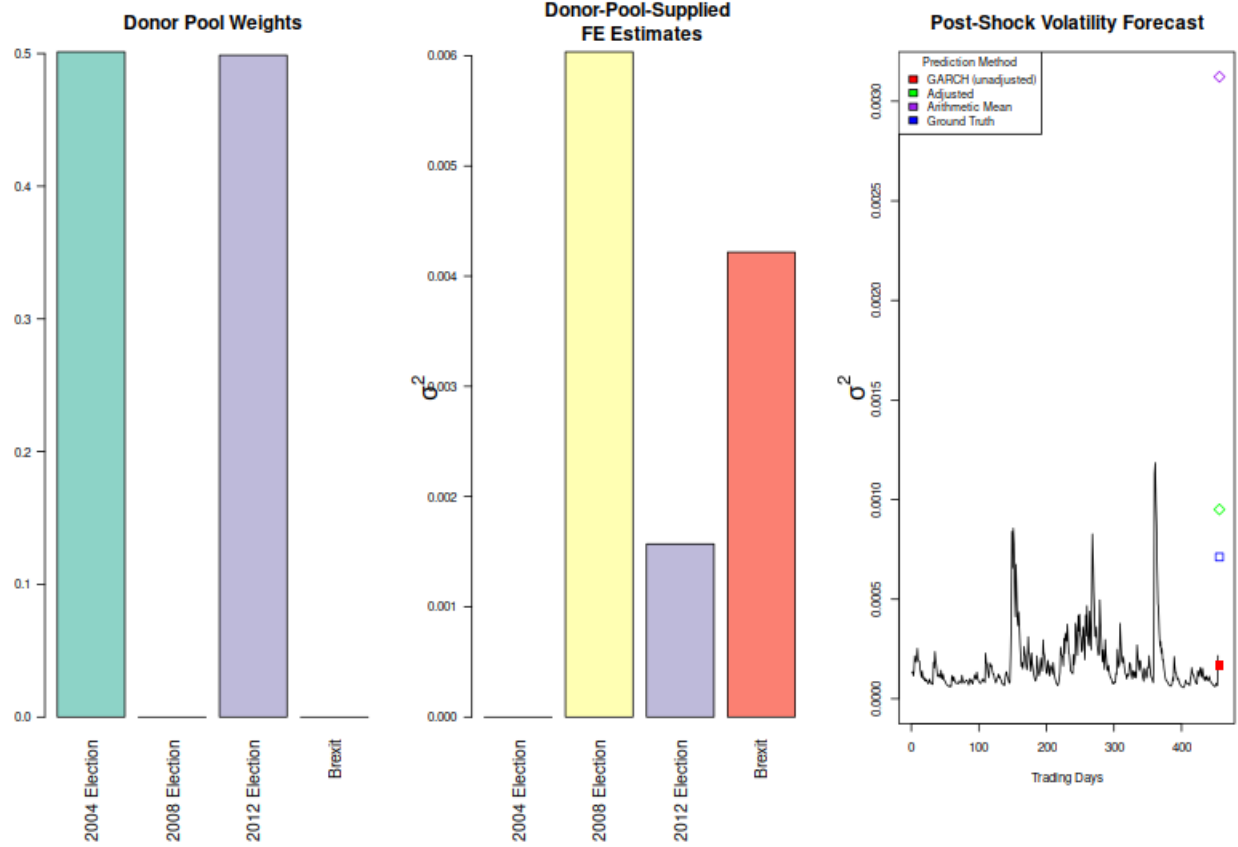

Figure 5: The volatility induced by the 2016 US election

We now discuss the three subplots in Figure 5 in order from left to right. On the left, we see that the distanced-based weighting places nearly equal weight on the 2004 and 2012 elections, with only negligible weight on the 2008 election and Brexit. Assuming an approximately correct specification of the covariates, this is interpreted to mean that even of the 2016 US election had a general climate of risk and tension less extreme than 2008 and Brexit and more similar to the 2004 and 2012 elections. In the middle plot, we notice that the fixed effect estimates for 2008, 2012, and Brexit are large, with only 2004 registering a near-zero fixed-effect estimate. The fixed-effect estimates quantify the amount of surprise the US election results delivered (strictly speaking, not only the presidential race but all November elections in the US with the ability to influence financial markets) under the assumption of a GARCH(1,1). As estimates gleaned from one data point, they are relatively high in variance. On the right, we observe in black the fitted values of σ^2 given the GARCH(1,1) for the time series under study. We also observe four points, all indicated by the legend: three predictions and the ground truth. We include the prediction derived by adjusting the GARCH(1,1) prediction by the arithmetic mean of the fixed-effect estimates. As is evident, the Synthetic Volatility Forecasting method comes reasonably close the ground truth. The

prediction is not only directionally correct; it far outperforms the unadjusted prediction. Remarkably, the arithmetic-mean based prediction here demonstrates the inherent risk in failing to weight each donor appropriately. The 2008 election and Brexit receive far more weight than is called for because simple averaging ignores the radically different conditions on the even of those two events.

Naturally, one would ask how sensitive this prediction is to at least two kinds of model specification: donor pool specification and covariate specification. There are two responses to these concerns. First, although the practitioner lacks a priori knowledge of the adequacy of the donors with respect to the time series under study, it is possible to gauge the diversity of the donor information by examining the singular values of the volatility profile. In the prediction presented here, the no singular value represents more than 50% of the sum of singular values. Indeed, the first four singular values descend from 50% to 25% to 21% to 5% of the the cumulative variation, indicating a low concentration or redundancy of information. Second, we follow [Steege et al. \[2016\]](#) in a executing a multiverse analysis. In particular, in the supplement, we carry out leave-one-out analyses on both the donor set and the covariate set. We here call out that with Brexit removed, the method places nearly all weight on the 2004 election, which has a fixed-effect estimate of almost zero. Hence, the prediction in [6](#) outperforms that unadjusted forecast but markedly undershoots the ground truth.

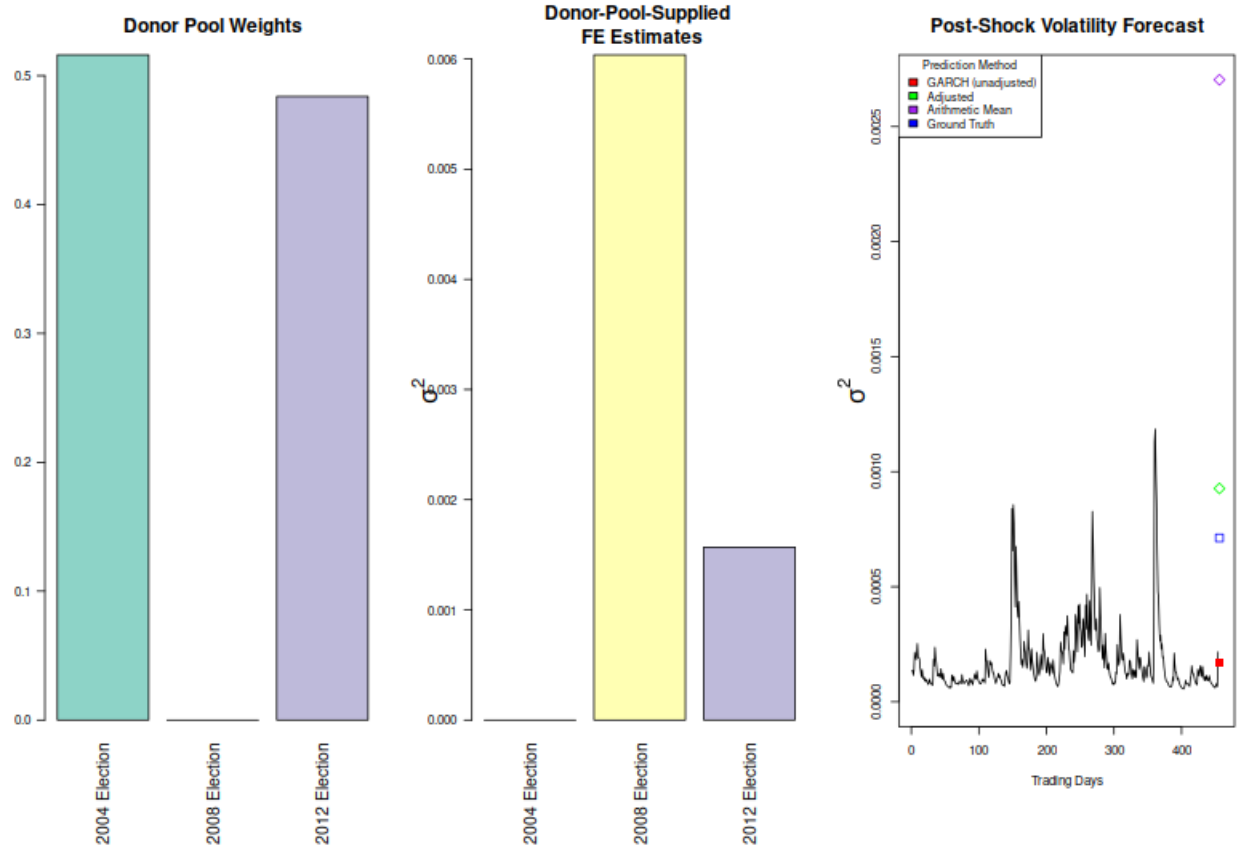

Figure 6: The volatility induced by the 2016 US election, Brexit excluded

6 Discussion

7 Supplement

We analyze the real-world example with Brexit included
